Gauge symmetry and the EMC spin effect

Abstract

We emphasise the EMC spin effect as a problem of symmetry and discuss the renormalisation of the $C = +1$ axial tensor operators. This involves the generalisation of the Adler-Bell-Jackiw anomaly to each of these operators. We find that the contribution of the axial anomaly to the spin dependent structure function $g_1(x, Q^2)$ scales at $O(\alpha_s)$. This means that the anomaly can be a large x effect in g_1 . Finally we discuss the jet signature of the anomaly.

1 Introduction

There has recently been a great deal of interest in polarised deep inelastic scattering as a result of the European Muon Collaboration (EMC [1]) measurement of the spin dependent proton structure function $g_1^P(x, Q^2)$. In the naive parton model g_1 is written as :

$$g_1(x) = \frac{1}{2} \sum_q e_q^2 \Delta q(x) \quad (1)$$

where

$$\Delta q(x) = (q^\uparrow + \bar{q}^\uparrow)(x) - (q^\downarrow + \bar{q}^\downarrow)(x) \quad (2)$$

is the polarised quark distribution. We write $\Delta q = \int_0^1 dx \Delta q(x)$. Then the flavour singlet contribution to the first moment of g_1 is the fraction of the proton's spin that is carried by its quarks in this parton model. The EMC data was combined with an earlier measurement of g_1 from SLAC [2]. After a smooth Regge extrapolation of their data ($g_1 \sim x^{-0.12}$) EMC determined the “spin content” to be [1]

$$\Delta u + \Delta d + \Delta s = 0.120 \pm 0.094(stat.) \pm 0.138(syst.) \quad (3)$$

which is consistent with zero and two standard deviations from the Ellis-Jaffe hypothesis, which says that strange quarks should not play a significant role.

There have been many suggestions of how to reconcile this EMC spin effect with quark model expectations. (The EMC experiment and its theoretical interpretation are discussed in detail in the reviews [3] and [4].) As a model independent statement, we can say that the spin effect is a violation of OZI in the flavour singlet channel [5]. In QCD the proton “spin content” (equ.(3)) is the flavour singlet axial charge g_A^0 ; it is the proton matrix element of the flavour singlet axial-vector current. Here we encounter the axial anomaly, which is an effect in the renormalised axial-vector current operator. (It is not present in the classical version of this operator.) The breakdown of the Ellis-Jaffe hypothesis for g_A^0 has led to the EMC spin effect being thought of as a first moment problem.

In truth the axial anomaly affects more than an just one operator. In the previous paper (ref. [6]) it was shown that the axial anomaly is a property of *each* moment of g_1 and not just the first moment; that is, the anomaly is relevant to the *whole structure function* $g_1(x, Q^2)$. This result involves the

generalisation of the axial anomaly to each of the higher spin axial-tensor operators $\bar{q}\gamma_\mu\gamma_5(iD_{\mu_1})\dots(iD_{\mu_{2n}})q$.

In this paper we develop these ideas further. We discuss the model independent properties of the anomaly contribution to g_1 that can be deduced from QCD alone. Thus we derive constraints that any future models of proton structure which include the anomaly will have to satisfy. Through-out this paper we develop the idea that the EMC spin effect is a problem in symmetry and emphasise that we have to be very careful to understand exactly what we mean by a parton in QCD.

In Sects.2 and 3 we focus on the role of the anomaly in the inclusive DIS cross section and work within the framework of the operator product expansion. In Sect.2 we explain precisely what it means to say that the anomaly is relevant to $g_1(x, Q^2)$. This allows us understand the subtle relationship between spin and g_1 . We show that the anomaly couples in a pointlike (local) manner to the hard photon in DIS. In Sect.3 we derive the renormalisation group properties of the anomaly in $g_1(x, Q^2)$ and show that it scales at $O(\alpha_s)$. These results suggest that the anomaly may be a large x effect in g_1 . An anomaly contribution at large x would be seen as an OZI breaking effect in the large x bins of the polarised DIS experiment. It would show up as a finite difference between g_1 and the C-odd spin dependent proton structure function g_3 [7], which is anomaly free and has the naive parton model interpretation $(q - \bar{q})^\uparrow(x) - (q - \bar{q})^\downarrow(x)$. In Sect.4 we discuss the jet signature of the anomaly.

2 Spin and g_1

In QCD the deep inelastic process is described by the operator product expansion (OPE) and the renormalisation group. The interesting physics of g_1 is in the flavour singlet part, which receives contributions from both quark and gluon partons, viz.

$$g_1(x, Q^2)|_S = \frac{1}{3}\sqrt{\frac{2}{3}}\int_x^1 \frac{dz}{z} \left[\Delta q_0(z, Q^2)C_S^q\left(\frac{x}{z}, \alpha_s(Q^2)\right) + \frac{1}{\sqrt{6}}\Delta g(z, Q^2)C_S^g\left(\frac{x}{z}, \alpha_s(Q^2)\right) \right] \quad (4)$$

The C-even, spin dependent quark $\Delta q_0(x, Q^2)$ and gluon $\Delta g(x, Q^2)$ distributions contain all the information about the target. They are defined with

respect to the operator product expansion so that their odd moments project out the target matrix elements of the renormalised spin odd, composite operators

$$2Ms_+(p_+)^{2n} \int_0^1 dx x^{2n} \Delta q_k(x, Q^2) = \langle p, s | [\bar{q}(0) \gamma_+ \gamma_5 (iD_+)^{2n} \frac{\lambda^k}{2} q(0)]_{Q^2}^{GI} | p, s \rangle_c \quad (5)$$

$$2Ms_+(p_+)^{2n} \int_0^1 dx x^{2n} \Delta g(x, Q^2) = \langle p, s | [\text{Tr } G_{+\alpha}(0) (iD_+)^{2n-1} \tilde{G}_+^\alpha(0)]_{Q^2}^{GI} | p, s \rangle_c \quad (n \geq 1) \quad (6)$$

Here $G_{\mu\nu}$ is the gluon field tensor, $\tilde{G}_{\mu\nu} = \frac{1}{2}\epsilon_{\mu\nu\alpha\beta}G^{\alpha\beta}$ is the corresponding dual tensor and $D_\mu = \partial_\mu + igA_\mu$ is the gauge covariant derivative in QCD. The kinematic variables p_μ and s_μ denote the proton momentum and spin vectors respectively (M is the proton mass). The superscript on the operators emphasises that they are quoted with respect to some gauge invariant regularisation scheme, and the subscript Q^2 indicates the subtraction point. (We have chosen to write the composite operators at the renormalisation scale $\mu^2 = Q^2$.) The association of $\Delta q_k(x, Q^2)$ with quarks and $\Delta g(x, Q^2)$ with gluons follows when we evaluate the target matrix elements in eqs.(5-6) in the light-cone gauge, where $D_+ \rightarrow \partial_+$.

The Wilson coefficient distributions $C(x, \alpha_s)$ are determined by the leading light-cone singularity in the product of the two electromagnetic currents on the light cone. They are target independent and describe the interaction of the hard photon γ^* with each of the quark and gluon partons, which are defined by eqs.(5-6). The coefficients may be calculated in perturbation theory, where one finds $C^q(x, \alpha_s) = \delta(x - 1) + O(\alpha_s)$ and $C^g(x, \alpha_s) \sim \alpha_s$.

It is known from unpolarised DIS experiments that the gluon distribution is concentrated at small x . In polarised DIS the hard photon scatters from a gluon via a quark-antiquark pair, described in $C^g(x, \alpha_s)$. This dissipates the gluon's already small momentum so that $\Delta g(x, Q^2)$ is relevant to g_1 only at small x ($x \leq 0.03$) [8]. It makes a negligible contribution to the measured sum rule between $x = 0.01$ and 1, where the three constituent quarks are expected to dominate. The clue to understanding the spin effect lies in the identification of the axial-vector current (and the higher spin axial tensors in equ. (5)) with spin. We need to understand how spin is realised in renormalised QCD.

The parton distributions are renormalised quantities which should always be quoted with respect to some regularisation. In general the introduction of

a regulator breaks some symmetry of the classical theory and this symmetry is not always restored in the continuum limit. (For a complete discussion of regulator theory we refer to the text of Zinn-Justin [9] and the lectures of Guichon [10].) This means that the symmetry properties of the *physical*, renormalised world in which we live are not identical to those of the classical Lagrangian. Noether's theorem which tells us about the symmetry of a classical Lagrangian may not be valid in the renormalised world. Using a different choice of regulator corresponds to retaining different symmetries after renormalisation so that two different renormalisation procedures can lead to worlds with different symmetry properties. This clash of symmetries is what is meant by an anomaly. The symmetries that must be preserved at all costs are Lorentz and gauge invariance.

It is well known that we cannot choose both gauge invariance and also to have chirality as a good quantum number (the Adler-Bell-Jackiw axial anomaly [11,12]). The axial anomaly predicts the decay rate for $\pi^0 \rightarrow 2\gamma$. This decay would be strongly suppressed without the anomaly. The axial anomaly is also relevant to our understanding of the U(1) problem in QCD [13] and the EMC proton spin data. It is important to realise that the anomaly is not restricted to an effect in the axial-vector current. An anomaly will manifest itself where-ever the quantum numbers of the relevant operator allow it. For example, any renormalisation calculation involves a subtraction scale - and this breaks the scale invariance of the classical theory. The only operators which are scale invariant are those which are not renormalised (ie. conserved currents and the other "soft" operators - the divergences of which just involve mass terms). The QCD evolution of the parton densities with increasing Q^2 and asymptotic freedom are intimately related to the scale anomaly.

We now consider the relationship between the axial anomaly and spin. Classically the axial vector current looks like a gauge invariant operator. The quark field operator transforms as

$$q(x) \rightarrow U(x)q(x)$$

and

$$\bar{q}(x)\gamma_\mu\gamma_5 \rightarrow \bar{q}(x)\gamma_\mu\gamma_5 U^\dagger(x) \quad (7)$$

under a given gauge transformation U . On the other hand, in quantum field theory the axial vector current operator is not just $\bar{q}(0)\gamma_\mu\gamma_5$ multiplied by

$q(0)$. It is a composite operator which has to be renormalised and there are extra divergences which are intrinsic to the operator itself. It turns out that one cannot renormalise the axial tensor operators in a gauge invariant way so that they describe spin at the same time. In general, for a given choice of renormalisation prescription R , the renormalised axial tensor operator differs from the gauge invariant operator by a multiple of a gauge-dependent, gluonic counterterm $k_{\mu\mu_1\dots\mu_{2n}}$, viz.

$$\left[\bar{q}(0)\gamma_\mu\gamma_5 D_{\mu_1}\dots D_{\mu_{2n}}q(0)\right]_R^R = \left[\bar{q}(0)\gamma_\mu\gamma_5 D_{\mu_1}\dots D_{\mu_{2n}}q(0)\right]_{Q^2}^{GI} + \lambda_{R,n} \left[k_{\mu\mu_1\dots\mu_{2n}}\right]_{Q^2} \quad (8)$$

where the coefficients $\lambda_{R,n}$ are fixed by the choice of renormalisation prescription. This axial anomaly was discovered for the axial vector current in QED. The operator product expansion is a rigorous result which follows from the completeness of gauge-invariant local operators - it is also describing a physical process. Thus we have to be careful to ensure that our parton distributions are quoted with respect to some gauge-invariant renormalisation prescription. (The scheme dependence of parton distributions is a statement about varying *within* the class of gauge invariant renormalisation prescriptions.)

Not only does the axial anomaly lead to a difference between the renormalised axial currents which preserve gauge invariance and chiral symmetry, but in addition the gauge invariant axial current is scale dependent (in this case the scale is Q^2). (The anomalous dimension of the first moment, Δq_0 , was first calculated for QCD by Kodaira [14].) This means that one cannot derive the generators of the spin algebra $SU(2)$ from it [4]. Thus, the gauge invariant axial-vector current does not measure quark spin in the proton. The axial-vector current which should be identified with spin is the renormalisation group invariant symmetry current [15], viz.

$$j_{5\mu}^S = j_{5\mu}^{GI} - k_\mu, \quad (9)$$

which satisfies the divergence equation $\partial^\mu j_{5\mu}^S = 2m_q \bar{q}i\gamma_5 q$. Here

$$k_\mu = \frac{\alpha_s}{2\pi} \epsilon_{\mu\lambda\alpha\beta} \text{Tr } A^\lambda (G^{\alpha\beta} - \frac{2}{3} A^\alpha A^\beta) \quad (10)$$

is the Chern-Simons current. The symmetry current $j_{5\mu}^S$ is *the* axial-vector current in a world where chirality is an exact symmetry and where gauge

invariance is not. One can say that *the gauge symmetry screens the spin of the quarks*.

Going beyond the axial-vector current, the distribution which does measure quark spin in the proton is defined with respect to the axial-tensor operators *in this same world* where chirality is an exact symmetry. In other words, the spin distribution is constructed formally using operators which are defined with respect to the same renormalisation prescription as the symmetry current $j_{5\mu}^S$. These S-prescription operators correspond to particular values of the coefficients λ_n in equ.(8), which were derived in ref.[6]. (These calculations were done in light-cone gauge $A_+ = 0$ using dimensional regularisation, where the anomaly becomes a problem of how to continue γ_5 into the regulator dimensions [16].) One finds

$$\lambda_{S,n} = -\frac{1}{(2n+1)(2n+2)} \quad (11)$$

and the two gluon part of $k_{\mu\mu_1\dots\mu_{2n}}$ is

$$\frac{\alpha_s}{\pi} i^{2n} \epsilon_{\mu\lambda\alpha\beta} A_a^\alpha \partial^\lambda \partial_{\mu_1} \dots \partial_{\mu_{2n}} A_a^\beta. \quad (12)$$

The spin distribution differs from the physical distribution $\Delta q(x, Q^2)$ measured in deep inelastic scattering by an anomalous gluonic term related to the $k_{\mu\mu_1\dots\mu_{2n}}$. This clash of symmetry between spin and gauge invariance defines the anomaly in g_1 .

We now illustrate this discussion by comparing g_1 with the other structure functions which are measured in DIS experiments. The axial anomaly is not relevant to the unpolarised quark distributions, which are described in OPE language by the operators $\bar{q}(0)\gamma_+(iD_+)^n q(0)$. It is also not relevant to the C-odd spin dependent structure function g_3 , which is the polarised version of F_3 . (In the naive parton model g_3 measures $(q - \bar{q})^\uparrow(x) - (q - \bar{q})^\downarrow(x)$.) Since g_3 is odd under charge conjugation, it can have no anomalous gluonic contribution. (Gluons are C-even.) This means that it does make sense to talk about F_1 , F_3 and g_3 in terms of quarks with explicit spin degrees of freedom - the clash of symmetry between gauge invariance and spin does not manifest itself in these structure functions. We write the gauge invariant distribution as

$$q_{GI}^\uparrow(x, Q^2) = (q_S^\uparrow + \frac{1}{4}\kappa)(x, Q^2) \quad (13a)$$

$$q_{GI}^\perp(x, Q^2) = (q_S^\perp - \frac{1}{4}\kappa)(x, Q^2) \quad (13b)$$

for both quarks and anti-quarks. Here $\kappa(x, Q^2)$ denotes the anomaly and the subscript S denotes the gauge-dependent spin distribution. The κ part of the quark distribution is relevant only to g_1 in deep inelastic scattering. It is constructed formally as follows. We consider the matrix element of the gauge dependent counterterm $k_{\mu\mu_1\dots\mu_{2n}}$ acting between nucleon states away from the forward direction. This matrix element will contain several form factors - some of which are sensitive to the Kogut-Susskind pole, which features in the solution of the U(1) problem [13]. Here we only need to consider the axial form factor which multiplies the Lorentz structure $s_\mu(p + p')_{\mu_1}\dots(p + p')_{\mu_{2n}}$, symmetrised over all indices. (We denote this form factor $\kappa_A^{(2n)}((p - p')^2)$; p_μ and p'_μ are the nucleon's initial and final momentum.) We take the forward limit $p'_\mu \rightarrow p_\mu$ and obtain a contribution $\kappa_A^{(2n)}(0)$ to the OPE matrix elements in equ.(5). The Mellin theorem is applied to these $\kappa_A^{(2n)}(0)$ to obtain the distribution $\kappa(x, Q^2)$. It is the difference between the measured quark distribution and the unphysical distribution which measures spin.

If we work in light-cone gauge then it follows that the three gluon part of k_+ (see eq.(10)) vanishes. Indeed, it was shown in ref.[17] that the gauge dependent operator k_μ coincides with a gauge invariant but non-local string operator in the axial gauge. It seems reasonable to postulate that $\kappa(x, Q^2)$ is invariant under gauge transformations within the axial gauge. In more general (eg. covariant) gauges one can show [15, 18] that k_μ is not invariant under gauge transformations. One should not try to isolate the nucleon matrix element of k_μ (or $\kappa(x, Q^2)$) from $\Delta q_0(x, Q^2)$.

The anomaly $\kappa(x, Q^2)$ describes part of the quark Fock state wavefunction of the proton where the quarks carry infinite momenta [19, 20]. For example, when the axial tensor couples to the proton via a gluonic intermediate state (Fig. 1) the anomaly is the purely pointlike part of the Adler-Bell-Jackiw triangle - hence the gluonic counterterm $k_{\mu\mu_1\dots\mu_{2n}}$. Since the anomaly is independent of quark flavour the same κ term is relevant to $u, d, s, c, \dots$. The anomaly κ varies only according to the "spin" and not the charge or flavour. Because the anomaly is flavour singlet it will induce some OZI violation where-ever it plays a role. This is the source of the EMC spin effect.

In DIS the physical distributions $q_{GI}^\uparrow(x, Q^2)$ and $q_{GI}^\perp(x, Q^2)$ couple locally to the hard photon via the OPE quark coefficient $C^q(x, \alpha_s)$. When we substi-

tute equ.(13) into equ.(4) it follows that each of the spin and κ components of the measured quark distribution have the same pointlike coupling to the photon. The anomaly couples to the photon in exactly the same way as a quark. Physically, this means that there is a new local interaction between the hard photon and a gluonic component in the proton which must be included into the QCD improved parton model (see Sect.4). This is despite the fact that the glue does not carry electric charge ! One can apply this argument in reverse to say that $C^q(x, \alpha_s)$ defines the OPE spin dependent quark distribution to include all partons which make a local interaction with the hard photon in DIS [21]. Clearly, the anomaly is an entirely different gluon effect in g_1 than $\Delta g(x, Q^2)$. We now discuss the renormalisation group properties of the anomaly in $g_1(x, Q^2)$.

3 Renormalisation group properties of the anomaly in g_1

At $O(\alpha_s)$ the measured parton distributions evolve with increasing Q^2 according to the GLDAP equations [22]

$$\begin{aligned} \frac{d}{dt} \Delta q_0(x, t) &= \frac{\alpha_s}{2\pi} \int_x^1 \frac{dz}{z} \left[\Delta q_0(z, t) P_{qq}^q\left(\frac{x}{z}\right) + 2N_f \Delta g(z, t) P_{gq}^q\left(\frac{x}{z}\right) \right] \\ \frac{d}{dt} \Delta g(x, t) &= \frac{\alpha_s}{2\pi} \int_x^1 \frac{dz}{z} \left[\Delta q_0(z, t) P_{qq}^g\left(\frac{x}{z}\right) + \Delta g(z, t) P_{gg}^g\left(\frac{x}{z}\right) \right] \end{aligned} \quad (14)$$

where $t = \ln Q^2$. The splitting functions have a probability interpretation in the light-cone gauge so that eg. $P_{gg}^q(x)$ is the probability for a gluon to branch into a quark-antiquark pair so that the quark (or antiquark) carries a fraction x of the gluon's momentum in the collinear direction. Formally, the GLDAP equations are related to the OPE in that the moments of the splitting functions reproduce the anomalous dimensions of the operators which appear in the OPE. It is important to emphasise that the spin dependent quark distribution which appears in the GLDAP equations is the gauge invariant one. This follows because the twist-two, gauge-invariant operators which define the parton distributions $\Delta q_0(x, Q^2)$ and $\Delta g(x, Q^2)$ mix under renormalisation independently of any gauge non-invariant operators [23].

We wish to disentangle an evolution equation for κ from the GLDAP equations. To do this we need to evaluate the anomalous dimension of the counterterm $k_{\mu\mu_1\dots\mu_{2n}}$, which is determined from its matrix elements between external quark and gluon states. In perturbation theory, the anomaly is a purely pointlike part of the one-loop vector (gluon), vector (gluon), axial-tensor amplitude (Fig.2). Hence there is one power of α_s which is intrinsic to $k_{\mu\mu_1\dots\mu_{2n}}$ (see equ.(12)). The anomalous dimension of $k_{\mu\mu_1\dots\mu_{2n}}$ starts at $O(\alpha_s^2)$; it is a two loop effect. Thus we deduce that the anomaly scales at $O(\alpha_s)$, viz.

$$\frac{d}{dt}\kappa(x, t) = 0. \quad (15a)$$

All of the QCD evolution of $\Delta q(x, Q^2)$ at $O(\alpha_s)$ is carried by its spin component. If we substitute eqs.(13) into eqs.(14) we can re-write the GLDAP equations as

$$\frac{d}{dt}\Delta g(x, t) = \frac{\alpha_s}{2\pi} \int_x^1 \frac{dz}{z} \left[(\Delta q_S(z, t) + \kappa(z, t)) P_{qq}^g\left(\frac{x}{z}\right) + \Delta g(z, t) P_{gg}^g\left(\frac{x}{z}\right) \right] \quad (15b)$$

$$\frac{d}{dt}\Delta q_S(x, t) = \frac{\alpha_s}{2\pi} \int_x^1 \frac{dz}{z} \left[(\Delta q_S(z, t) + \kappa(z, t)) P_{qq}^q\left(\frac{x}{z}\right) + 2N_f \Delta g(z, t) P_{gg}^q\left(\frac{x}{z}\right) \right] \quad (15c)$$

Since the physical distribution $\Delta q_0(x, t)$ evolves to zero at large x in the asymptotic limit $Q^2 \rightarrow \infty$ it follows that the spin component must evolve to $-\kappa(x)$ at infinite Q^2 and finite x .

The two loop splitting function corresponding to the anomaly can be derived as follows. The spin dependent distribution $\Delta q^{(g)}(x, Q^2)$ of a gluon is evaluated in perturbation theory by calculating the graph in Fig.2, where we work in the light-cone gauge $A_+ = 0$. This calculation has been carried out in refs.[20, 24, 6]. There is a contribution from finite k_T^2 between the quark mass squared and Q^2 , which has the usual partonic Fock state interpretation, and also the anomaly. The anomaly is a purely pointlike part of the triangle amplitude; it makes a contribution $-\frac{\alpha_s}{\pi} N_f (1-x)$ to $\Delta q^{(g)}(x, Q^2)$ [6], where N_f is the number of quark flavours. The two loop splitting function for $q \rightarrow \kappa$ is given by folding this factor with the splitting function for $q \rightarrow g$, viz. $P_{qq}^g(x) = \frac{4}{3}(2-x)$. We find

$$P_{qq}^\kappa(x, \alpha_s) = -\frac{4\alpha_s}{3\pi} N_f \int_x^1 \frac{dz}{z} (1-z) \left(2 - \frac{x}{z}\right) \quad (16)$$

Equ.(16) is the generalisation of Kodaira's two loop anomalous dimension of the axial vector current to the higher spin axial tensor operators. Kodaira's result [14] can be obtained by taking the first moment of $P_{qq}^\kappa(x)$. The two loop splitting function for $g \rightarrow \kappa$ is evaluated in the light-cone gauge by folding the anomalous $-\frac{\alpha_s}{\pi}N_f(1-x)$ factor with the splitting function for $g \rightarrow gg$, viz. $P_{gg}^g(x)$.

Now we can deduce the general properties of the anomaly in g_1 . We have stressed that the spin and anomalous components of $\Delta q(x, Q^2)$ are not separately gauge invariant. This means that the anomaly κ is an intrinsic part of the measured spin dependent quark distribution in the inclusive DIS cross section. The evolution equation (15a) says that the piece which is shifted between q_S and κ scales at $O(\alpha_s)$. We can make gauge transformations which increase the magnitude of κ at the expense of the spin part over all x . We have shown that the anomaly scales at $O(\alpha_s)$ in $\Delta q(x, Q^2)$ and also that it couples to the hard photon in exactly the same way as a quark (via the tree amplitude or $C^q(x, \alpha_s)$ in OPE language). Hence the anomaly makes a scaling contribution to g_1 .

The anomaly has all the characteristics of a large x effect. Certainly there is no good theoretical reason to suppose that it is confined to small x in the g_1 data like the ordinary gluon distribution $\Delta g(x, Q^2)$. A large x anomaly would be seen as an OZI breaking effect in the large x bins of the polarised DIS experiment. It would mean that the spin of the three constituent quarks is screened by the gauge symmetry of QCD. Since the anomaly is not present in g_3 it would be most helpful to obtain data on this C-odd spin dependent proton structure function. A large x anomaly would show up as a finite difference between g_1 and g_3 at large x [6, 7].

4 The anomaly and the parton model: what is a parton?

It is very important to understand how our hitherto formal discussion of the anomaly applies to exclusive processes like jet production. Up to this point we have been discussing the inclusive DIS cross-section and this allowed us to use the operator product expansion. In the OPE treatment the measured quark distribution includes all those partons which interact locally

with the hard photon (ie. they couple to the photon via $C^q(x, \alpha_s)$). The OPE parton distributions can be separated experimentally by taking precise DIS data over a range of Q^2 and then applying the evolution equations to fit a phenomenological parametrisation to each of $\Delta q_0(x, Q^2)$ and $\Delta g(x, Q^2)$. If we wish to make predictions for jet production we normally use the QCD improved parton model.

The improved parton model is based on the factorisation of mass singularities. These singularities arise when partons branch in the collinear direction and can be absorbed into a parton density, which is often *assumed* to be equal to the OPE parton distribution evaluated in the light-cone gauge $A_+ = 0$. The DIS cross section is then written as the convolution of these parton densities with a “hard” part of the phase space for photon-parton scattering. The improved parton model deals with explicit quark and gluon spin degrees of freedom - it has no κ . This conflict arises because the improved parton model was formulated as a problem of collinear partons whereas the anomaly is strictly a non-collinear effect. One would never find κ by appealing to the improved parton model alone. In other words, factorisation is necessary but not sufficient to completely define the parton model for helicity dependent processes in QCD [6].

Let us illustrate the problem by considering two-quark-jet production in polarised photon gluon fusion. We work in perturbation theory to $O(\alpha_s)$. If we apply the operator product expansion to this process then the total cross section is written as the sum of the OPE quark distribution $\Delta q^{(g)}(x, \mu^2)$ and the gluonic Wilson coefficient $C^g(x, \frac{Q^2}{\mu^2}, \alpha_s)$, where $\mu^2 \leq Q^2$ is the renormalisation scale. As we mentioned in Sect.3 the anomaly is included in $\Delta q^{(g)}(x, \mu^2)$; it describes a contact interaction with the target gluon.

In the QCD improved parton model we would say that the gluon distribution $\Delta g(x, \mu^2)$ is characterised by two-quark-jet events with large $k_T^2 \geq \mu^2$ [24]. On the other hand, the anomaly corresponds to part of the phase space corresponding to two-quark-jet events with $k_T^2 \sim Q^2$. This contact interaction has been interpreted by some authors [20, 26] to mean that the anomaly is a local probe of the gluon distribution $\Delta g(x, Q^2)$ in polarised DIS. Here we take a different view. It is important in this example of photon gluon fusion to be precise about when we regard the gluon as the *target* and when it is a *parton*. In the OPE language, the gluon should be regarded as the target when it is used to write down the quark distribution $\Delta q^{(g)}(x, Q^2)$ (which

includes the anomaly). It is a parton when it corresponds to the gluonic coefficient $C^g(x, \alpha_s)$. The large k_T^2 jets which are associated with the anomaly in the photon gluon fusion process are coming from the shattering (or jet-fragmentation) of the *target* gluon and we distinguish these jets from the jets which are associated with the interaction of a gluon *parton* with the hard photon (ie. the coefficient $C^g(x, \alpha_s)$ in the OPE, which is universal to all targets in DIS). This may appear semantics in the photon gluon fusion process, where a gluon is both the target and a parton. However, when we have a hadronic target like the proton one should be careful about saying that the anomaly is characterised *only* by two-quark-jet events with large $k_T^2 \sim Q^2$. We need to understand the gluonic part of the hadron wavefunction.

There is some part of the hadron wavefunction which includes a gluon which is close to being in an asymptotic state (ie. sufficiently off shell) so that it may be treated perturbatively - as if we were we doing QED. Only in this case (when α_s is small) can we reliably say that the anomaly has a two quark jet signature. (The forward matrix elements of k_μ are gauge invariant in QED and the anomaly does measure the helicity of the gluon in this case.) In general the wavefunction is non-perturbative and here one has to worry about gauge invariance. Since the q_S and κ components of the physical spin dependent quark distribution are not separately gauge invariant (we consider an arbitrary gauge) it makes no sense to associate the anomaly κ exclusively with two-quark jet events and the q_S parton with one jet events. (One cannot gauge transform a one jet event into a two jet event!)

It appears that there is some critical coupling α_s^c such that the anomaly is characterised by two-quark jet events for $\alpha_s \leq \alpha_s^c$ and some (if not all) times by one jet events for $\alpha_s \geq \alpha_s^c$. This latter effect generates the non-perturbative anomaly contribution to g_A^0 , which was found by Forte [27]. (One has to be careful not to push the gauge dependence argument so far as to claim that the non-perturbative q_S and κ components of $\Delta q(x, Q^2)$ have the same jet signature. This would be true if $\kappa(x, Q^2)$ could be gauge transformed to zero in any arbitrary gauge. There seems no reason to suppose such a strong hypothesis.) Thus, we find that the relationship between the OPE and improved parton model breaks down for spin dependent processes. The pointlike interaction between the hard photon and the gluonic component described by $\kappa(x, Q^2)$ contributes to the semi-inclusive cross-section for one-quark jet events! This means that one has to be careful when using perturbative QCD to predict absolute jet cross sections for helicity dependent

processes involving polarised initial state hadrons.

Acknowledgements

It is a pleasure to thank V. N. Gribov, L. Mankiewicz, N. N. Nikolaev, A. Schafer and A. W. Thomas for many discussions on the spin problem. I am grateful to N. N. Nikolaev for helpful comments on the manuscript.
